Abstract

Background: Fibromyalgia, rheumatoid arthritis, spondyloarthritis and Sjögren's syndrome are chronic rheumatic diseases with very different clinical characteristics, but which share symptoms such as pain and fatigue. The aim of the study was to examine the impact of the disease on psychological adaptation in fibromyalgia compared to other rheumatic diseases (rheumatoid arthritis, spondyloarthritis and Sjögren's syndrome).

Method: In a multicenter study, 165 women with rheumatic diseases (48 with fibromyalgia, 47 with rheumatoid arthritis, 47 with spondyloarthritis, 23 with Sjögren's syndrome) completed the GHQ-28 (emotional distress), FSS (fatigue), FIQ (impact of the disease), CSQ (coping), and MINI (comorbidity with DSM IV axis-I disorders). We used the Kruskal-Wallis test, Mann-Whitney U-test and the Chi² test to compare comorbid anxiety and depressive disorders, and to compare the impact of the disease on patients' mental well-being and daily life and adjustment (coping strategies).

Results: Anxiety and depressive disorders were more common in fibromyalgia patients; they had higher scores on impact of the disease, physical symptoms, pain and fatigue than rheumatoid arthritis patients, and reported more fatigue than patients with spondyloarthritis. Overall, they used more maladaptive coping strategies (less use of *Distancing from pain* than patients with rheumatoid arthritis and spondyloarthritis, less use of *Ignoring pain sensations*, and more use of *Catastrophizing* than those with rheumatoid arthritis). No differences were found between fibromyalgia and Sjögren's syndrome on impact and adjustment.

Conclusions: Compared to other rheumatic diseases, fibromyalgia has a greater impact on daily life; patients have more difficulty adjusting to the disease and generally use poorer strategies to cope with pain.

Keywords: Fibromyalgia, rheumatic diseases, impact of the disease, psychological adjustment, coping, rheumatic diseases.

Introduction

Fibromyalgia, rheumatoid arthritis, spondyloarthritis and Sjögren's syndrome are chronic diseases with different clinical characteristics, but which share symptoms such as pain and fatigue. Unlike the other three rheumatic diseases, which are clearly recognizable by their clinical, imaging and biological features, fibromyalgia is a diagnosis of exclusion, which can only be established once other conditions have been ruled out and could affect the way that patients cope and adjust to the disease. All these diseases have a major impact on patients' daily life, requiring considerable effort to cope with the illness. As most existing studies comparing fibromyalgia with other rheumatic diseases only consider it when it is associated with another rheumatic disease, they do not allow a clear distinction to be made between how patients adjust psychologically to each disease.

Studies have examined symptoms of fibromyalgia in inflammatory or autoimmune rheumatic diseases and the relationship with disease activity (1, 2). Other studies found that fibromyalgia patients had higher pain scores (3, 4) and greater fatigue variability (5) than patients with rheumatoid arthritis. Pain in rheumatoid arthritis is associated with depression, while in fibromyalgia, it is linked more to stress levels (6). Hence, pain and fatigue levels seem to be predictors of depression in rheumatoid arthritis, whereas distress markers are predictors of fibromyalgia (7). Patients with fibromyalgia reported more depressive episodes and anxiety disorders (panic disorder, post-traumatic stress disorder) than patients with rheumatoid arthritis (8, 9), and had higher scores on emotional distress, depression, anxiety and stress (10, 11). Patients with spondyloarthritis perceived a change in their daily life due to physical disability, while patients with fibromyalgia experienced these changes due to pain, anxiety, fatigue and disability (12). Finally, patients with fibromyalgia express lower general well-being than those with spondyloarthritis. They also report a poorer quality of life than patients with Sjögren's syndrome (particularly social and physical dimensions) (13). So far, no study has compared

these diseases in terms of coping strategies. The aim of this study was to compare fibromyalgia, rheumatoid arthritis, spondyloarthritis and Sjögren's syndrome regarding *(i)* their impact on daily life, and *(ii)* psychological adjustment (coping strategies).

Material and method

Participants

The inclusion criteria were: a) women aged over 18 and under 70 years; b) duration of disease between 6 months and 10 years; c) social security cover; d) no difficulty communicating in French, and e) to have been informed about the study by her doctor. A rheumatologist systematically confirmed the diagnosis using international disease classification criteria: ACR (14) and FIRST criteria (15) for fibromyalgia; ACR criteria for rheumatoid arthritis (16); ASAS criteria for spondyloarthritis (17); and Vitali et al.'s criteria (18) for Sjögren's syndrome. He also ensured that patients met the inclusion and exclusion criteria for the study. The exclusion criteria were: association with another rheumatic diseases, HIV infection, history of cancer or blood malignancy, thyroid dysfunction and other endocrinopathies, viral hepatitis and all other comorbidities that the investigator considered to be severe (chronic heart failure, renal failure, respiratory failure, etc.).

Measures

To estimate the prevalence of anxiety and depressive disorders, we used the *Mini International Neuropsychiatric Interview* (MINI) (19, 20). This is a structured diagnostic interview exploring the presence or absence of the main DSM-IV axis-I disorders. It indicates comorbid anxiety and depressive disorders.

First, to assess the emotional distress caused by the disease, we used the *General Health Questionnaire* (GHQ) (21, 22). This is a self-administered questionnaire evaluating the level of

distress experienced by the individual using a 4-point Likert scale. Its 28-item version investigates four areas of subjective emotional distress: *Somatic symptoms*, *Anxiety-insomnia*, *Social dysfunction, Severe depression.*

To assess the impact of the illness on daily life, first we used the *Fibromyalgia Impact Questionnaire* (FIQ) (23, 24), which is a self-administered questionnaire with 10 items assessing the physical, psychological and social impact of the illness on the quality of the patient's daily life using an 11-point Likert scale. Although this questionnaire is designed specifically for fibromyalgia, we assumed that it would be relevant for comparison of fibromyalgia with other diseases in these aspects. Secondly, to assess the common somatic symptoms of the disease in daily life, we used the *Visual Analogic Scale* (VAS), which assesses the level of pain on a scale of 0 to 10, and the *Fatigue Severity Scale* (FSS) (25), a self-administered 9-item questionnaire assessing the level of fatigue and its functional consequences using a 7-point Likert scale.

Finally, to assess how patients adjust to living with a rheumatic disease, we used the *Coping Strategies Questionnaire* (CSQ) (26, 27), a 21-item self-administered questionnaire assessing five specific cognitive strategies of coping with pain: *Distraction* (thinking of things that can divert attention from pain), *Catastrophizing* (worrying and focusing only on the negative aspects of pain), *Praying* (saying to yourself that you have to hope and pray that the pain will one day go away), *Distancing from pain* (trying to perceive sensations other than pain), and *Ignoring pain sensations* (denying that pain makes us suffer and affects us). Usually, problem-focused coping strategies (*Distancing from pain*, *Ignoring pain sensations*) are better for health outcomes, while emotion-focused strategies (avoidant coping: *Distraction*, *Catastrophizing*, *Praying*) are less favorable.

Procedure

The data were collected in three French hospitals (Tours, Orleans and Paris) by a rheumatologist and a psychologist. Informed written consent was obtained from all the participants and an ethics committee approved the study.

Data analysis

Internal consistency of all the questionnaires was good, with a Cronbach's alpha coefficient >.70. As the variables were not normally distributed in each group, we used non-parametric analysis techniques. First, we compared comorbid anxiety and depressive disorders in fibromyalgia and the other rheumatic diseases (rheumatoid arthritis, spondyloarthritis and Sjögren's syndrome). To this end, we used the Chi² test for categorical variables or Fisher's exact test when there were fewer than five subjects in a sample. Next, we conducted a Kruskal-Wallis test (one-way ANOVA on ranks) to compare the impact of the disease on daily life and psychological adjustment in the different rheumatic diseases. After that, we performed a Mann-Whitney U test to compare fibromyalgia with the other diseases for continuous variables. We also conducted a hierarchical cluster analysis using Ward's linkage method with squared Euclidian distance, followed by a k-means cluster analysis, which allocates each case to the cluster with the nearest center point. To compare clusters, we used the Kruskal-Wallis test (including a pairwise post-hoc test). Statistical analyses were performed with Statistica® version 12.

Results

Participants' characteristics

The sample comprised 165 French women with rheumatic diseases, mean age 47.24 years (± 10.77 years, range 21 to 65), with 4 sub-groups: 48 women with fibromyalgia (Mean age = 47.98 ± 9.69, range 25 to 65), 47 with rheumatoid arthritis (Mean age = 50.89 ± 11.31, range

24 to 65), 47 with spondyloarthritis (Mean age = 42.30 ± 9.30, range 21 to 59), and 23 with

Sjögren's syndrome (Mean age = 48.30 ± 11.48, range 25 to 64). There was a significant

difference in age across groups (H (3, 165) = 16.88, p<.001). The average education level

corresponded to completion of high school, with no significant difference between groups.

Average duration of disease was 4.13 years (± 2.83, range .5 to 10) with significant differences

between groups (H (3, 165) = 9.40, p<.05). However, the effects of age and duration of disease

were small and limited and indicated only a tendency towards a slight decrease of the functional

repercussions with the evolution of the disease and the age of the patient (data not shown). Forty

percent of the women were menopausal (35% with fibromyalgia, 49% with rheumatoid arthritis,

26% with spondyloarthritis, and 61% with Sjögren's syndrome), with significant differences

between groups (Chi² = 10.26, p<.05). For patients with fibromyalgia, the FIRST criterion mean

was 5.92 (±.28, range 5 to 6) and tender points mean was 16.79 (±2.30, range 11 to 18).

Internal consistency

The internal consistency of all scales was evaluated for each rheumatic disease.

Cronbach's alpha coefficients were acceptable (between .69 and .94), as shown in Table 1.

Descriptive data are provided in Table 2.

Please Insert Tables 1 and 2 here

Comparison of the prevalence of anxiety and depressive disorders in patients with fibromyalgia and other rheumatic diseases

Psychiatric disorders were assessed with the MINI in order to establish the prevalence

of comorbidities. Tables 3 and 4 show only significant results in the comparison of comorbid

anxiety and depressive disorders in fibromyalgia and the other rheumatic diseases.

Fibromyalgia patients had experienced more recurrent (past) major depressive episodes than

those with other diseases (rheumatoid arthritis, spondyloarthritis or Sjögren's syndrome).

Anxiety disorders (agoraphobia and generalized anxiety disorder) were more common in fibromyalgia than in spondyloarthritis or Sjögren's syndrome; post-traumatic stress disorder was more common in fibromyalgia than in rheumatoid arthritis.

All analyses were then processed with menopausal and premenopausal women separately. Menopausal women with fibromyalgia presented with significantly more depressive disorders than those with other disorders, with the exception of menopausal women with spondyloarthritis who presented with more major depressive episodes with melancholic features. For premenopausal women, only the results for recurrent major depressive episodes were significant. There was a greater prevalence of current generalized anxiety disorder among premenopausal women with fibromyalgia than among those with other rheumatic diseases. This was the same for menopausal women, except in comparison with Sjögren's syndrome. There was a higher prevalence of agoraphobia among premenopausal women with fibromyalgia than among those with rheumatoid arthritis or spondyloarthritis. There was a higher prevalence of agoraphobia among, menopausal women with fibromyalgia than among those with Sjögren's syndrome.

Please Insert Tables 3 and 4 here

Comparison of the impact of the disease and the coping strategies used by patients with fibromyalgia and other rheumatic diseases

First, we observed overall effects. The ANOVA revealed significant differences between groups in the impact of the disease on daily life (H (3, 165) = 13.42, $p<.05$), *Somatic symptoms* (H (3, 165) = 11.64, $p<.01$), fatigue (H (3, 165) = 36.00, $p<.001$), and on the coping strategies of *Distancing from pain* (H (3, 165) = 10.75, $p<.05$) and *Ignoring pain sensation* (H (3, 165) = 12.76, $p<.01$). Next, we performed a Mann-Whitney U-test to compare fibromyalgia with each of the other rheumatic diseases. Table 5 shows the results of comparative analyses

for emotional distress, impact of the disease, pain, fatigue, and coping strategies. Patients with fibromyalgia had higher scores than those with rheumatoid arthritis for emotional distress (GHQ-28) (*Somatic symptoms* and *Severe depression*), for perceived fatigue, and impact of the disease. Patients with fibromyalgia were more likely to use a *Catastrophizing* strategy and less likely to use *Distancing from pain* and *Ignoring pain sensation* than patients with rheumatoid arthritis. They experienced greater pain, fatigue and more *somatic symptoms* and used the *Ignoring pain sensations* strategy less than patients with spondyloarthritis. There was no difference in the perception of the impact of the disease and in adjustment between fibromyalgia and Sjögren's syndrome patients.

Please Insert Table 5 here

Menopausal women with fibromyalgia reported a significantly greater impact of disease, pain and fatigue than those with rheumatoid arthritis, greater fatigue and less *Distancing from pain* than spondyloarthritis patients, and greater *Distraction* and *Ignoring pain sensations* than Sjögren's syndrome patients. Premenopausal women with fibromyalgia reported more *Somatic symptoms* and fatigue than those with rheumatoid arthritis and more fatigue than those with spondyloarthritis. Menopausal women seemed to be more affected by the disease, pain and fatigue than premenopausal women, but comparisons between the two groups were not significant (available on supplementary data).

Major depressive episodes and emotional distress

In order to examine the relationship between major depressive episodes (MDE) diagnosed with the MINI, emotional suffering evaluated by the General Health Questionnaire (GHQ), and pain or the strategies for coping with pain, we first investigated the functional impact of the presence or absence of current or recurrent MDE (Table 6). Next, we conducted a k-means cluster analysis. A three-cluster solution seems to reflect the particularities of each

group while remaining easy to interpret (Figure 1). Cluster 1 was characterized by an absence of mood disorder (current or past MDE) and low or moderate scores on *Severe depression*, *Anxiety/insomnia*, *Somatic symptoms* and *Social dysfunction*. Cluster 2 included patients presenting with mood disorders (current and past MDE) and high scores on GHQ subscales. Patients in Cluster 3 had a past MDE, no current MDE, and moderate scores on GHQ subscales.

Please Insert Table 6, Figure 1 and 2 here

Cluster 1 was composed of 79 women (mean age 46.30 ± 11.24 years, range 23-65) with the highest rate of professional activity (86%; Chi² test, $p < .01$), and the lowest invalidity rate (8%, ns). It included 8 fibromyalgia patients (10.1%), 27 rheumatoid arthritis patients (34.2%), 31 spondyloarthritis patients (39.2%), and 13 Sjögren's syndrome patients (16.5%). Cluster 2 was composed of 51 women (mean age 48.43 ± 9.26 years, range 28-65 years) with the lowest rate of professional activity (63%), and the highest invalidity rate (22%). It included 23 fibromyalgia patients (45.1%), 8 rheumatoid arthritis patients (15.7%), 13 spondyloarthritis patients (25.5%) and 7 Sjögren's syndrome patients (13.7%). Cluster 3 (n = 34) was intermediate between Clusters 1 and 2, comprising patients with a mean age of 47.88 ± 11.95 years (range 21-65 years), 79% in professional activity, and an invalidity rate of 15%. It comprised 17 fibromyalgia patients (50.0% of the group), 11 rheumatoid arthritis patients (32.4%), 3 spondyloarthritis patients (8.8%) and 3 Sjögren's syndrome patients (8.8%). The clinical characteristics of patients in Cluster 1 were also better than those in Cluster 2, while those of Cluster 3 were between the two (See Figure 2). Significant differences on Kruskal-Wallis tests are indicated in the figure, and we also performed pairwise post-hoc tests to assess the differences between groups (group interactions).

Most fibromyalgia patients were included in the second (47.9%) or third (35.4%) cluster, with only 16.7% in the first. The majority of rheumatoid arthritis patients were in the

first cluster (58.7%) (vs 17.4% and 23.9% in Clusters 2 and 3 respectively). The situation was similar for both spondyloarthritis patients (66.0% in Cluster 1 vs 27.7% in Cluster 2 and 6.4% in Cluster 3) and Sjögren's syndrome patients (56.5%, 30.4%, and 13.0% in Clusters 1, 2 and 3 respectively).

Discussion

Consistent with previous studies (2-5), patients with fibromyalgia showed higher levels of pain, fatigue, perceived emotional distress, anxiety and depressive comorbidity (with a significant suicidal risk), and they made less use of the strategies of *pain distancing* and *ignoring pain* than patients with other rheumatic diseases.

In fibromyalgia, levels of pain and fatigue are markers of distress (7), and fatigue is associated with a reduction in positive affectivity, which plays a role in reducing the impact of pain (28). Symptoms of anxiety and depression in fibromyalgia are linked to physical symptomatology and functional disability and to an increase in pain and tender points (29-31). Depression appears to be fairly reactive to fibromyalgia (32) and the pain experienced by patients increases the risk of a major depressive episode (33). There is a significant bilateral causal link between depression and pain: pain depresses the patient and depression promotes pain (34-36). In this study, the emotional distress of fibromyalgia patients was associated with social dysfunction and somatic symptoms, and patients experienced more comorbid anxiety and depressive disorders, especially recurrent major depressive episodes and agoraphobia, than patients with other rheumatic diseases. The greater anxiety (agoraphobia, post-traumatic stress disorder and generalized anxiety disorder) and higher incidence of depressive disorders (major depressive episodes) could partly explain why fibromyalgia patients feel more affected by their illness in daily life than patients with other rheumatic diseases and could play a role in the way they adjust to the condition. Maladaptive coping strategies also contribute to the strengthening

of mood disorders (e.g. 33, 37, 38). In this study, the comparative table with and without MDE (current or past MDE) and the nonhierarchical cluster analysis highlight the importance of mood disorders in fibromyalgia patients and their association with levels of pain, fatigue and maladaptive coping strategies. Our results also show the importance of checking for past MDEs due to their association with emotional distress. They can be indicators of the vulnerability of patients, but it is difficult to establish whether the functional repercussions are the result of mood disorders or represent aspects of behavior that are closely related to fibromyalgia.

In the present study, fibromyalgia patients used *Catastrophizing* more than patients with rheumatoid arthritis, *Distancing from pain* less than patients with rheumatoid arthritis, and *Ignoring pain sensations* less than patients with rheumatoid arthritis and spondyloarthritis. Patients with fibromyalgia rarely use active coping strategies to improve their quality of life (39) and are more likely to resort to maladaptive coping strategies than patients with other rheumatic diseases. The use of maladaptive strategies is an indication of how patients give up trying to manage pain or assign this responsibility to an outside source (34). *Catastrophizing* is linked to the intensity of pain and the severity of depression, which are markers of maladjustment (34, 40).

The comparison between fibromyalgia and rheumatoid arthritis shows that fibromyalgia patients feel the effects of the disease more strongly (higher level of pain, fatigue and impact of illness on daily life) and present with more anxious and depressive disorders, fewer adaptive coping strategies, and more *catastrophizing* than patients with rheumatoid arthritis. Rheumatoid arthritis is considered as the archetype of rheumatic diseases and is easier to diagnose than fibromyalgia. The lack of objective diagnostic criteria for fibromyalgia can often lead patients to consult multiple practitioners before the diagnosis is considered. This doctor shopping (or "medical nomadism") results in multiple and often conflicting opinions, which may give patients a sense of being misunderstood and of injustice, that they are given no support or

consideration for their suffering, and fear about their future (41-43). This would in turn lead to an increase in emotional insecurity (44) and a lack of understanding of their physical state, resulting in an inability to cope with the disease on a daily basis and heightened anxiety and depressive disorders.

This acute perception by patients of the effects of fibromyalgia on their daily life and their poor use of coping strategies could also be seen in connection with personality, which plays an essential role in how we interpret our environment (health beliefs and underlying dysfunctional thoughts), notably *Neuroticism,* which is the tendency to perceive reality as threatening and painful and is connected with psychological distress and mood disorders. *Neuroticism* has been shown to be higher in fibromyalgia patients than in those with other rheumatic diseases (45) and could explain the greater presence of depression in fibromyalgia.

There was no difference between fibromyalgia and Sjögren's syndrome patients in the way they perceived the impact of their illness on their daily life, and in the use of coping strategies. This could be explained by the difficulty of establishing a diagnosis in both these diseases, often delayed for several years because of the variability of the clinical features and the insidious progress of Sjögren's syndrome and the lack of objective diagnostic criteria for Fibromyalgia, which often leads to loss of confidence, discouragement and feelings of uncertainty about the future. Although these diseases differ in severity, prognosis and treatment, it appears that the difficulty of making a diagnosis could have a negative impact on how patients cope and adjust to the disease.

Menopausal women accounted for 40% of our sample. Overall, they presented with more depressive disorders than premenopausal women, but the differences were not statistically significant. It is widely accepted that menopausal transition may affect women and increase the risk of mood disorders (e.g. 46), but other factors must be taken into account, such as age, duration of the disease, somatic symptoms, type of rheumatic disease, etc. While the menopause

can interact with anxiety or pain, it can also accentuate the phenomena of dryness of the mouth and vagina, which cause the patient real discomfort, particularly in Sjögren's syndrome; as these symptoms can be difficult to talk about, they may not be adequately treated. Menopause should be systematically included in the medical monitoring of rheumatic diseases.

The limitations of the study are mainly related to the self-assessment of the impact of the illness on daily life and coping strategies and the sample size. The subgroup of Sjögren's syndrome patients was small (it is a much rarer disease) and the inclusion and exclusion criteria restricted the number of participants.

Conclusion

This study shows that patients with fibromyalgia have higher levels of pain, greater incidence of anxiety, somatic symptoms and depressive disorders, and a worse quality of life than patients with other rheumatic diseases. It also shows that patients with fibromyalgia have greater difficulty adjusting to the illness, with significant consequences on outcome. Helping patients develop appropriate coping strategies should be part of the management of rheumatic diseases, particularly fibromyalgia and Sjögren's syndrome. It would be desirable for rheumatology departments to have a psychologist on their staff to systematically check for any history of mood disorders (due to their association with levels of pain, fatigue and maladaptive coping strategies) and more generally, to assess how patients adapt to their disease.
